***Abstract*— Autonomous swarm algorithms have been studied extensively in the past several years. However, there is little research on the effect of injecting human influence into a robot swarm—whether it be to update the swarm's current goals or reshape swarm behavior. While there has been growing research in the field of human-swarm interaction (HSI), no previous studies have investigated how humans interact with swarms under communication latency. We investigated the effects of latency both with and without a predictive display in a basic swarm foraging task to see if such a display could help mitigate the effects of delayed feedback of the swarm state. Furthermore, we introduce a new concept called *neglect benevolence* to represent how a human operator may need to give time for swarm algorithms to stabilize before issuing new commands, and we investigate it with respect to task performance. Our study shows that latency did affect a user's ability to control a swarm to find targets in the foraging task, and that the predictive display helped to remove these effects. We also found evidence for neglect benevolence, and that operators exploited neglect benevolence in different ways, leading to two different, but equally successful strategies in the target-searching task.**

I. INTRODUCTION

Robotic swarms are made up of small, homogeneous robots with limited capabilities that act through local interactions to collectively achieve a variety of behaviors including flocking [1], [2], [3], [4], deployment [5], [6], and foraging [7], [8]. The principal advantage of swarm robotic systems is that, due to their large numbers and emergent behaviors, they are quite robust to failure of individual robots. However, for using swarm robotic systems for human-supervised missions, it is imperative to understand the basic tenets of human-swarm interaction (HSI). Since we are concerned with human control of swarms (a special class of multi-robot systems), we will restrict ourselves to literature on HSI. For a more general in-depth review of HRI, please see the survey paper [20] and references therein.

There have been few user studies investigating HSI, and even fewer using operators that did not themselves design the system. One of the first papers in the field of HSI was [21], which allowed an operator to designate any robot in the swarm as a leader, and use it to guide the remainder of the swarm around as they followed using a flocking algorithm. This idea of using designated leaders and followers has since become a well-known method of swarm control [12], [15]. Since then, human-swarm control has also been studied for several specific applications, such as search and localization [8], battlefield operation [13], and even alongside humans in firefighting situations [14]. Other studies [22], [23], [24], [25] have investigated haptic control of swarms moving in formation, whereby an operator supplies continuous input to the swarm and receives force feedback and (possibly) visual information about the state of the swarm. However, none of the above report any controlled user study investigating how operator commands influence the dynamics of a swarm operating under an otherwise autonomous algorithm.

In the extant literature, there are some studies that do investigate HSI using user studies [9], [10], [22], [23]. However, these studies either assume that perfect state information is fed back to the operator without any delay, or that continuous input must given through a haptic device, either of which may be invalid in practice if their are other demands on communication or operator attention. Therefore, in this paper, we study HSI under realistic assumptions of communication latency and localization heading errors.

Algorithms that generate collective behavior in swarm robotic systems take time to stabilize and exhibit the collective behavior after they start using their local interaction rules. This is a key aspect in human control of swarms, since this self-stabilization implies that the effect of a human input to the swarm may not be immediately apparent to the human. Moreover, the swarms may be operating anywhere from a few feet to thousands of miles away, with limited communication hardware (e.g., radios with limited transmission range). Thus, there may be some delay in transmitting the state of the robots to the humans and the command of the human to the robots. There may also be errors made by individual robots in executing the human inputs. The communication latency and the input error along with the self-stabilizing nature of the emergent behaviors of robotic swarms create challenges for the operator in understanding the current state of the swarm and the effect of his or her command. The extant literature on HSI [8], [9], [10], [11], [12], [13], [14], [15] have not studied the performance and behavior of human operators in the presence of delayed

This research has been sponsored in part by AFOSR FA955008-10356 and ONR Grant N0001409-10680.

information transmission between the swarm and the human and vice versa. Therefore, in this paper, we create an experimental scenario to study the effects of latency and error on human performance in controlling swarm robotic systems. We also study the use of predictive displays to mitigate the effect of latency. To the best of our knowledge, this is the first controlled experimental study that tries to understand human performance and behavior for human swarm interaction under communication delay.

Since the swarms require time to stabilize after an operator command is issued, it is possible for operator commands to have different effects depending on the state of the swarm. The human operator has to influence the swarm without adversely disturbing the swarm—a task that can be further hindered by high communication latencies. To capture the idea that humans may need to observe the evolution of the swarm state before acting, we investigate a novel concept called *neglect benevolence*, whereby neglecting the swarm to allow for stabilization before issuing new commands may be beneficial to overall mission performance. This concept is analogous to *neglect tolerance* [16], [17] in human-robot interaction (HRI). Neglect tolerance is defined as the time a human can neglect a robot in a multi-robot system of independently operating robots (i.e. non-coordinating robots) without degradation in system performance. For neglect tolerance, it is assumed that the performance of an individual robot degrades with time and hence the attention of the operator needs to be scheduled so that the time between servicing robots is minimized [18], [19]. In contrast, neglect benevolence captures the concept that it may be beneficial to leave the swarm alone for a certain length of time after issuing an instruction to allow the behavior to stabilize (since the swarm state may not degrade monotonically with time). In Section III, we discuss how the users exploit neglect benevolence in multiple ways to develop successful strategies for target finding.

In the rest of this paper, we first give a brief discussion of related work in Section **??**. In Section II we describe our experimental scenario in detail. We present and discuss the results of our experiments in Section III, and in Section IV we present our conclusions and outline avenues of future work.

II. TASK DESCRIPTION

Our study is designed to look at the ability of a human operator to effectively influence a swarm operating under algorithms that require time to exhibit emergent behaviors. We created a simple foraging task that requires users to direct a swarm around an open environment using instructions to change swarm heading and flocking constraints. We also use this study to look at the effect of communication latency in the swarm-operator channel on this ability. Latency can be caused by multiple factors, including lag due to hardware issues onboard the individual robots or the time for the information to disperse or aggregate amongst the swarm.

A. The Environment

We use three different environments of size 100x100 meters divided into six regions (fig. 1), with each region containing one of three target frequencies: *low* (0-4), *medium* (5-9), or *high* (10+). The target distribution is different across the search missions that each participant solves, i.e. different regions may have different frequencies between missions, but there are always 40 targets in total. The interface participants use to issue commends to the swarm does not show either the region boundaries or their frequencies; however, participants do receive a worksheet for each trial indicating the target density of each region.

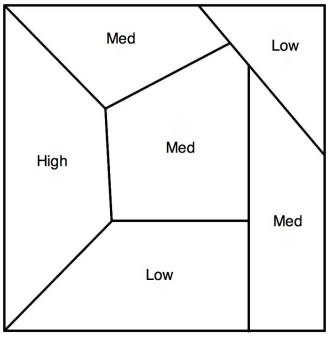

Fig. 1. An example worksheet the participant receives before a condition. Shows each of the six regions with the approximated number of targets the robots could expect to find in each. $Low = 1-4, Med = 5-10, High = 10+$.

We use Stage v. 3.2.2 [26] to simulate the environment, the targets, and a swarm of 40 differential drive P2AT robots. Robot controllers are implemented using the Robot Operating System (ROS) [27]. Each robot is equipped with a color sensor with a range of 4 meters, which allows it to detect the colored targets, and an additional, simulated sensor that allows the robots to sense the location of a neighbor within 4 meters. The latter allows each robot to estimate the direction of motion of its neighbors from repeated observations of their location.

The graphical user interface is also implemented in ROS. Each robot transmits its position and observations from its color sensor to the user interface. After six or more robots detect a target simultaneously, it is displayed on the map at the centroid of the robots that sensed it. The total number found is displayed on the side of the screen at all times.

B. Human Influence

Users can influence the swarm with three commands: *stop*, *heading*, and *apply-constraints*. The *stop* command simply instructs the robots to stop their motors. The *heading* command broadcasts a global heading to the swarm. To simulate a localization error every robot interprets the global heading with respect to a local coordinate frame to compute its goal heading. The orientation of this local coordinate frame differs from the true orientation of the robot by an error sampled from the Gaussian distribution $\mathcal{N}(0, \frac{4\pi}{9})$.

Upon receiving the command, the robots turn toward their respective goal heading and begin moving (fig. 2a). In order

to correct for the erroneous interpretations of the global heading, each robot also executed a consensus algorithm at a frequency of 0.5 Hertz. Robots sense the direction of motion of their neighbors and update their goal heading to the average goal heading of their neighbors and themselves.

Following the consensus algorithm, robots will slowly change their heading to the average of their neighbors, and after some number of steps, every robot that is connected to the rest of the swarm will be moving in the same direction as the others (fig. 2b). The amount of time to reach consensus depends on how tightly connected the swarm members are. In a fully connected swarm, this would average out the Gaussian error in the goal heading in one cycle of the consensus algorithm. Although the consensus algorithm is guaranteed to converge even without fully connected swarms, the point of convergence may not be the average goal heading at the start. Therefore, some error bias can remain in the final goal heading of the swarm.

Finally, the user could issue an *apply-constraints* command, which applies biologically-inspired flocking constraints similar to those in [1], [2], and [15]. These constraints force robots to repel from each other if they were closer then 1.5 meters, and otherwise attract to neighbors further than 3 meters. Only the closest 5 neighbors are considered for these constraints. If a robot was between 1.5 and 3 meters from each of it's neighbors, they proceeded toward to goal heading dictated by the consensus algorithm (fig. 2c). The above is illustrated in Algorithm 1.

Applying the constraints serves two necessary functions: the repulsive force spaces out the swarm to give better coverage, and the attractive force helps prevent the swarm from splitting into many disconnected subgroups. However, these constraints were not automatically on for the duration of the study because of the need for a swarm to have time to reach consensus. Because the consensus algorithm required robots to sense the positions of their neighbors over time in order to get accurate heading estimates, if constraints were applied automatically following a heading command, much of this movement would be due to enforcing the 1.5 to 3m separation between robots. This introduces significant noise to the consensus algorithm and increases the error dramatically. Therefore, allowing the operator to activate constraints gives him or her to opportunity to observe the swarm and decide when the benefits given by the constraints are more important than further consensus.

end while

C. Experimental Design

The experiment consists of three conditions—the *control*, *latency*, and *predictive* conditions. In all conditions, the operator begins with an open environment and the swarm of 40 robots positioned randomly in a 10x10 meter box at the center.

In the *control* condition, there is no latency in either of the human-to-swarm or swarm-to-human channels. In the *latency* condition, however, each channel has a latency of 10 seconds, which provides a realistic latency that is easily noticeable by a participant and forces them to make accurate predictions if they wish to influence the swarm effectively. This means that operator-issued commands will not reach the robots until 10 seconds after issuing, and the state of the swarm displayed in the interface for the user is 10 seconds old. In the *predictive* condition, the latency remains present; however, the interface gives the user a prediction of where each member of the swarm will be in 20 seconds (the time it takes for an operator's command to travel to the swarm and the result to return to the operator) by taking the heading and speed (which is a constant 0.5 m/s) of each swarm member and extrapolating the robot's position that far in the future (fig. 3). The prediction does not extend past the point the robots would perform the user's command. In other words, if the user issued a command 3s ago, the prediction will only show the swarm state 17s further into the future (which is 7 seconds ahead of the actual state).

Each participant has a different environment for each of these conditions, and the order of both the conditions and the maps are randomized for each participant in order to

Fig. 2. Shows the swarm in each of the three possible states. After the user issues a heading command, each robot begins to move in that direction; however, before the reach consensus, the Gaussian heading error means they will not all be moving the same direction (a). After enough rounds of the consensus algorithm, the robots have all converged on an approximately identical heading (b). Finally, after the user issues the flocking constraints, the robots attempt to stay between 1.5 and 3m of each other, and thus cover more area (c).

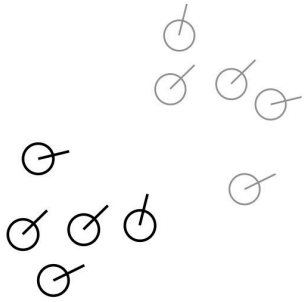

Fig. 3. An illustration of the predictive display condition. The interface projected a lighter shadow ahead of each robot to predict for the user where the robot would be in l seconds, or when the next command is received.

remove any learning biases. 21 participants (8 men and 13 women) were recruited from the University of Pittsburgh and surrounding areas to participate in the study. Each participant was given a short explanation of the controls and goals of the study and a 10-minute training session to familiarize themselves with the interface, after which they completed each of the three conditions.

III. RESULTS AND DISCUSSION

In order to properly measure swarm cohesion and determine both the short- and long-term effects of user-issued commands, we logged the state of each robot every second, which allowed us to compute the total coverage of the swarm for both each heading command, and for each condition overall. We then used total coverage and number of targets found out of 40 as global measures of success for a participant. Total coverage is defined as the area of the environment that was visible by 6 sensors simultaneously at some point during the mission. Furthermore, we looked for evidence of neglect benevolence directly by investigating how the state of consensus at the time of operator commands interacted with the swarm's progress along the goal heading, and measures of swarm cohesion, such as the number of connected components and the average communication graph degree (i.e., average number of neighbors for the robots in the swarm).

The overall mission performance for each participant is measured in terms of the number of targets found. In the *control* condition participants found 19.86 targets on average. In the *latency* condition participants found 16.71 targets on average, significantly fewer than in the *control* condition ($p = .021$). Finally, in the *predictive* condition participants found 18.86 targets on average, not significantly different from the *control* condition ($p = .467$), see Figure 4. These results show that the latency of 10 seconds impedes operator performance in the *latency* condition and that the predictive display in the *predictive* condition prevents this performance impediment.

The behavior of operators can be distinguished by the frequency, duration, and timing of the *heading* and *apply-constraints* instructions. The frequency is given by the total number of instructions during a condition, and the two durations we analyzed were the average time between a *heading* and a subsequent *apply-constraints* command (hereafter referred to as time to constraints), or the next *heading* command (duration). The timing of instructions is an important concept, since it relates to the state of the swarm at the time of the instruction—meaning two commands of the same type can lead to drastically different effects depending on when they were issued.

The duration of heading instructions differ significantly between the conditions. The *control* condition with a mean duration of 26.6 seconds differs significantly from the *latency* ($p = 0.00164$) and *predictive* ($p = 0.0039$) which have a mean of 42.4 and 40.2 respectively. The *latency* and *predictive* conditions do not differ significantly ($p = 0.68$),

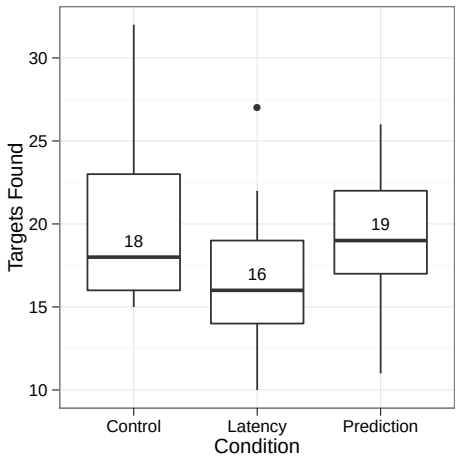

Fig. 4. A boxplot of the number of targets found across conditions. The median number of targets is shown above the median line.

see Figure 5. For the heading instructions, frequency and duration have an obvious relationship since at any point in time only one heading instruction is executed.

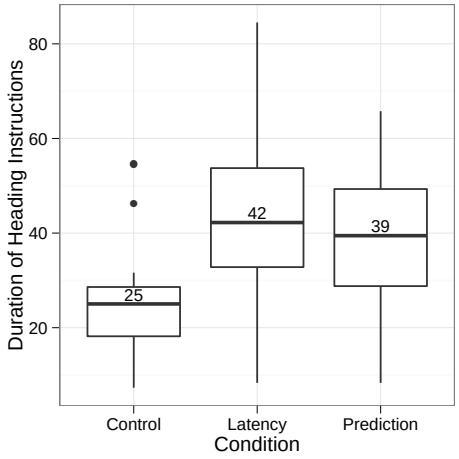

Fig. 5. A boxplot of heading command durations across conditions. The median duration time in seconds is shown above the median line.

The *apply-constraints* instruction, however, can be more flexible, and operators may decide to issue constraints at any point in time after a *heading* command, or issue a new *heading* command without activating constraints at all. On average, a participant did not use any constraints for 39.42% (std. deviation of 30% and median of 39.41%) of their heading instructions, with no differences ($p > 0.7$) across conditions or between any two conditions. There are, however, significant differences across participants. In fact, combining all conditions, participants cover the entire spectrum, from using constraints for only 9% of *heading* commands up to using constraints after every one. Exactly 2 participants used constraints for 0% to 25% of *heading* commands, 6 for 25% to 50% of *heading* commands, 6 for 50% to 75%, and 7 for 75% to 100%. To investigate the effect

of the application of constraints, we grouped all missions with a high, medium, or low number of constraint instructions, i.e. 100% to 78% (high), 78% to 45% (medium), 45% to 0% (low) of headings commands for which constraints were applied. The boundaries were chosen to obtain equal sized groups (across conditions and participants). Table I summarizes the main results comparing these groups. Performance in terms of targets found does not differ between these groups, but the total area swept is significantly different, with fewer constraints (low) leading to less overall area that is covered by at least six sensors. On the other hand, many constraints (high) lead to a larger error between the heading of the swarm and the operator's goal heading, and fewer constraints (low) have more heading instructions leading to a consensus (74%) and more robots in a consensed state when the next instruction is issued (69%). In addition, more constraints lead to fewer connected components (2.12) and more neighbors for each robot (4.79) on average.

These results suggest that operators employ different strategies to find a larger number of targets. Some operators use constraints often and earlier to cover a wider area at the expense of higher heading errors, while others prefer to give the consensus more time, leading to a smaller deviation from the operators goal heading at the expense of coverage and swarm cohesion.

The differences in operator behavior between the *control*, *latency*, and *predictive* conditions are only significant for heading duration (as shown above) and the average time to constraints. A difference between either of the two conditions with a 10 second latency and the control was expected, since operators have to wait 10 seconds to obtain information in order to decide whether constraints are needed, and since the activation of constraints takes 10 seconds to arrive at the swarm. In fact, across all instructions, only 27% in the latency condition and 30% in the *predictive* condition have constraints activated later than 20 seconds, meaning that, for the remaining instructions, the operator issued the constraints prior to seeing the effect of the heading instruction on the swarm. The *predictive* condition has a significantly higher time to constraint ($p = 0.0218$) to the *control* condition with a mean of 19.39 and median of 19, see Figure 6. However, the *latency* condition is not significantly different ($p = 0.12$)

from the *control* condition with means of 16.91 and 11.15 and medians of 13 and 12. This indicates that there is some adaptation of strategies to conditions and that operators are often using the activation of constraints regardless of whether they have information about the swarm state. Our results above, however, show that operators already employ a wide variety of strategies that differ across participants. There is no significant interaction between the conditions and the low, medium, and high constraint groups on the number of targets found ($p = 0.3158$) nor on the measures in Table I.

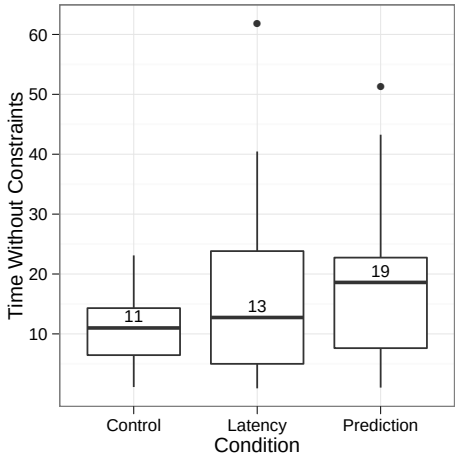

Fig. 6. The average time to the activation of constraints. The two black dots represent outlier trials, where two participants issued constraints considerably later on average in the *latency* and *prediction* conditions, respectively.

A closer look at the duration of heading instructions can cast some light on the effects of different behaviors on the swarm state. Participants with either short, medium or long heading instructions, see Table II, show a similar pattern than the activation of constraints in Table I. The targets found does not differ significantly, but the area covered with at least 6 sensors does ($p < .001$), demonstrating that the short duration group compensates for less area swept by using fewer constraints activated and thus a smaller heading error.

Altogether, the above results clearly show support for neglect benevolence. Early activation of constraints leads to larger heading errors and a mismatch between the operators desired direction and the direction of the swarm. However, letting a swarm move with constraints active for a long time, without interrupting with new heading instructions, improves its cohesion and ability to cover area with its sensors. Frequent and short commands, on the other hand, may provide an operator more control over the direction by providing new inputs more frequently, but this leads to an increase in the number of connected components and disturbs the swarms cohesion by frequently deactivating constraints. In other words, we have shown that operators develop strategies around the neglect benevolence of the swarm with respect to these two processes that either stabilize the consensus and lower the heading error, or stabilize the flocking formation and improve coverage. It appears operators were able to use either method to their advantage and obtain a good performance. While we found some behavioral differences across control, latency, and predictive conditions, there is no direct evidence that latency affects some strategies differently than others.

We also demonstrated that a predictive display helps participants overcome the latency issues and find the same number of targets as they would without any latency present. There are two possible explanations for this finding. First, the predictive display provided the operators the ability to time their new *heading* instructions appropriately. If, for instance, an operator wanted to explore a region entirely, the prediction allowed them to see when the swarm would reach the edge of the region—or the edge of the map—and issue the command so that the swarm would receive the new heading at the proper time. Without the prediction, the operator has less information on which to make this decision. Second, the predictive display also allowed users to easily identify groups that may break off, and to identify the state of consensus of the swarm. If a swarm of robots is about to split in two because two subgroups are moving at different headings and may not reach consensus before splitting, the predictive display will show these two subgroups 20 seconds in the future—at which point their splitting, if unaltered by constraints or consensus, is readily apparent. Similarly, if the swarm has not reached consensus, the predictive display will show them significantly more detached and spread out in 20 seconds time, whereas the prediction for a swarm at consensus will look more or less similar to the current state.

IV. CONCLUSIONS AND FUTURE WORKS

Overall, this study provides support for the idea of neglect benevolence. The possible commands in the study provided both costs and benefits depending on the state of the swarm at the time the commands were issued. Frequent redirections of the swarm provided the user more control over the direction, and thus location, of the swarm, but sacrificed other characteristics necessary for a foraging or exporation task performed with a swarm, including total coverage and swarm cohesion.

This led to two basic types of operators. Some prefer a higher accuracy for the heading of the swarm, while other

prefer a constrained motion in formation. Due to the nature of the swarm algorithms and localization errors, a high accuracy and a good formation using constraints are not possible simultaneously. Therefore, participants had to decide which characteristics were more important. For the present study, both strategies achieved success; however, other tasks may be better achieved with one of the other. Future research could help determine for which tasks each of the above strategies is most suitable, and should also employ qualitative questions that query the operators on their preferred strategy, as well as their insights into the swarm behavior and the effect of their instructions.

Furthermore, latency had a negative effect on the number of targets found, but only if the operator was not supported by a predictive display, demonstrating that the prediction enabled operators to regain some of the original performance. Latency also seemed to significantly impact the frequency with which operators issue commands. As this is the first study to investigate latency in HSI, future work should address latency issues for human control of other tasks and swarm algorithms, varying latency times, and using different methods of predicting future swarm states.
